Background: Deep learning for functional equations

Equilibrium conditions as functional equations

Most theoretical models in economics with equilibrium conditions can be written as functional equations:

- Take some function(s) $\psi \in \Psi$ where $\psi : \mathcal{X} \to \mathcal{Y}$ (e.g. asset price, investment choice, best-response).
- ullet Domain ${\mathcal X}$ could be state (e.g. dividends, capital, opponents state) or time if sequential.
- The "model" is $\ell: \Psi \times \mathcal{X} \to \mathcal{R}$ (e.g., Euler and Bellman residuals, equilibrium FOCs).
- The solution is the root of the model (residuals operator), i.e., $0 \in \mathcal{R}$, at each $x \in \mathcal{X}$.

Then a solution is a $\psi^* \in \Psi$ where $\ell(\psi^*, x) = 0$ for all $x \in \mathcal{X}$. How do we find an approximate solution?

Example: recursive formulation of the neoclassical growth

An example of a recursive case:

- Domain: x = [k] and $\mathcal{X} = \mathbb{R}_+$.
- Solve for the optimal policy $k'(\cdot)$ and consumption function $c(\cdot)$: So $\psi: \mathbb{R} \to \mathbb{R}^2$ and $\mathcal{Y} = \mathbb{R}^2_+$.
- Residuals are the Euler equation and feasibility condition, so $\mathcal{R} = \mathbb{R}^2$:

$$\ell(\underbrace{\begin{bmatrix} k'(\cdot) & c(\cdot) \end{bmatrix}}_{\equiv \psi}, \underbrace{k}_{\equiv x}) = \underbrace{\begin{bmatrix} u'(c(k)) - \beta u'(c(k'(k))) \left(f'(k'(k)) + 1 - \delta \right) \\ f(k) - c(k) - k'(k) + (1 - \delta)k \end{bmatrix}}_{\text{model}}$$

• Finally, $\psi^* = [k'(\cdot), c(\cdot)]$ is a solution if it has zero residuals on domain \mathcal{X} .

Classical solution method for functional equations

Quick review of collocation-like methods:

- 1. Pick finite set of D points $\hat{\mathcal{X}} \subset \mathcal{X}$ (e.g., a grid).
- 2. Choose approximation $\hat{\psi}(\cdot; \theta) \in \mathcal{H}(\Theta)$ with coefficients $\Theta \subseteq \mathbb{R}^M$ (e.g., Chebyshev polynomials).
- 3. Fit with nonlinear least-squares

$$\min_{\theta \in \Theta} \sum_{x \in \hat{\mathcal{X}}} \ell(\hat{\psi}(\cdot; \theta), x)^2$$

If
$$\theta \in \Theta$$
 is such that $\ell(\hat{\psi}(\cdot;\theta),x) = 0$ for all $x \in \hat{\mathcal{X}}$ we say $\hat{\psi}(\cdot;\theta)$ interpolates $\hat{\mathcal{X}}$.

- 4. The goal is to have good **generalization**:
 - The approximate function is close to the solution outside of $\hat{\mathcal{X}}$.
 - In high dimensions this becomes very important.

A deep learning approach: I

Recall we need a parametric function $\hat{\psi}(\cdot; \theta) \in \mathcal{H}(\Theta)$:

- Deep neural networks are highly-overparameterized functions designed for good generalization.
- Number of coefficients much larger than the grid points $(M \gg N)$.
- Example: one layer neural network, $\hat{\psi}: \mathbb{R}^Q \to \mathbb{R}$:

$$\hat{\psi}(x;\theta) = W_2 \cdot \sigma (W_1 \cdot x + b_1) + b_2$$

- $W_1 \in \mathbb{R}^{P \times Q}$, $b_1 \in \mathbb{R}^{P \times 1}$, $W_2 \in \mathbb{R}^{1 \times P}$, and $b_2 \in \mathbb{R}$.
- $\sigma(\cdot)$ is a nonlinear function applied element-wise (e.g., $\max\{\cdot,0\}$, Sigmoid, Tanh,...).

A deep learning approach: II

- $\Theta \equiv \{b_1, W_1, b_2, W_2\}$ are the coefficients, in this example M = PQ + P + P + 1.
- Making it "deeper" by adding another "layer":

$$\hat{\psi}(x;\theta) \equiv W_3 \cdot \sigma(W_2 \cdot \sigma(W_1 \cdot x + b_1) + b_2) + b_3.$$

- Think of deep neural networks as parametric functions.
- Architecture of the neural networks can be flexibly informed by the economic insight and theory.
 - The **Symmetry** paper heavily relies on this.

Concerns regarding over-parameterization

"I remember my friend Johnny von Neumann used to say, with four parameters I can fit an elephant, and with five I can make him wiggle his trunk."

Enrico Fermi

"The best way to solve the problem from practical standpoint is you build a very big system ... basically you want to make sure you hit the zero training error."

Ruslan Salakhutdinov, SI 2017

- If the number of parameters is much larger than the grid points (i.e. $M \gg N$), there might be many interpolating solutions.
- So which solution(s) are we going to find? .
 - I will come back to this in the **Spooky** paper.

Exploiting Symmetry in High-Dimensional Dynamic Programming

Motivation

- Most dynamic models in macro (and other fields) deal with either:
 - Representative agent or few agents.
 - A continuum of agents.
- However, many models of interest in macro (IO and trade) deal with finite (but large) number of agents and idiosyncratic/aggregate uncertainty:
 - Industry dynamics with many firms, agents and industries, even models with networks.
 - Heterogeneous agent labor models (e.g., overlapping generations, different types).
- These models are becoming increasingly popular, but:
 - They pose computational challenges as we add more agents.
 - No (non-heuristic) algorithm exists providing global solutions in the presence of aggregate uncertainty.

Challenges: the curse of dimensionality in equilibrium models

Three components to the curse of dimensionality with many agents (Bellman, 1958, p. IX)

- 1. The cardinality of the state space is enormous.
 - With 266 state variables, with 2 values per state (zero and one), we have more arrangements (2²⁶⁶) than the estimated number of protons in the universe.
- 2. With idiosyncratic and aggregate shocks we need to calculate high-dimensional conditional expectations.
- 3. Finding equilibrium paths to the steady-state (ergodic distributions) are extremely hard in high-dimensions.

Contribution

Inspired by economic theory, providing novel method for **globally** solving high-dimensional heterogeneous agent models with **aggregate shocks** which relies on:

- 1. A symmetry present in many heterogeneous agent models, i.e., exchangeability of agents.
 - Example: In general equilibrium models the Walrasian auctioneer removes indices.
- 2. **Concentration of measures**, something that resembles the law of large numbers to deal with conditional expectations (very fast).
 - More agents makes it easier to forecast the evolution of distributions.
- 3. Show how to implement the symmetry when using deep neural networks.

With these we globally solve a model with 10,000 (and even more) agents which was not possible before.

Literature Review

- Deep learning as a functional approximation: Maliar et al. (2019), Fernández-Villaverde et al. (2022), Duarte (2018), Azinovic et al. (2022), Han et al. (2021) (a mean-field approach).
- Symmetry in statistics and machine learning: Bloem-Reddy and Teh (2020), Zaheer et al. (2017), and Yarotsky (2018).
- Symmetry in computer science (MDP/RL): Ravindran and Barto (2001) and Narayanamurthy and Ravindran (2008), van der Pol et al. (2020).
- Symmetry in micro and games: Jovanovic and Rosenthal (1988), Hartford et al. (2016)

Application

How do we pick our application to show how all this works?

- In terms of application, there are two routes:
 - 1. Introducing a sophisticated application where the method "shines".
 - 2. Or, applying it to a well-known example.
- If I tell you about a sophisticated application, how do we know our "solution" method works?
- So we study a well-known example (with a twist).
- Study the more sophisticated applications in future projects.

Our application

A variation of the Lucas and Prescott (1971) model of investment under uncertainty with N firms.

Why?

- 1. Ljungqvist and Sargent (2018), pp. 226-228, use it to introduce recursive competitive equilibria.
- 2. Simple model that fits in one slide.
- 3. Under one parameterization, the model has a known Linear-Quadratic (LQ) solution, which gives us an exact benchmark.
- 4. By changing one parameter, the model is nonlinear, with no known solution. Our method handles the nonlinear case as easily as the LQ case with high accuracy.

Investment under uncertainty

- Industry consisting of N > 1 firms, each producing the same good.
- Firm of interest produces output x (x units of capital).
- Thus, the vector $X \equiv [X_1, \dots X_N]^{\top}$ is the production (or capital) of the whole industry.
- The inverse demand function for the industry is, for some $\nu \geq 1$ (this is our twist):

$$p(X) = 1 - \frac{1}{N} \sum_{i=1}^{N} X_i^{\nu}$$

- The firm does not consider the impact of its individual decisions on p(X).
- Adjustment cost: investing u has a cost $\frac{\gamma}{2}u^2$.
- Law of motion for capital $x' = (1 \delta)x + u + \sigma w + \eta \omega$ where $w \sim \mathcal{N}(0, 1)$ an i.i.d. idiosyncratic shock, and $\omega \sim \mathcal{N}(0, 1)$ an i.i.d. aggregate shock, common to all firms.
- The firm chooses u to maximize $\mathbb{E}\left[\sum_{t=0}^{\infty} \beta^t \left(p(X)x \frac{\gamma}{2}u^2\right)\right]$.

Recursive problem

The recursive problem of the firm taking the exogenous policy $\hat{u}(\cdot, X)$ for all other firms as given is:

$$v(x,X) = \max_{u} \left\{ p(X)x - \frac{\gamma}{2}u^2 + \beta \mathbb{E}\left[v(x',X')\right] \right\}$$
s.t. $x' = (1-\delta)x + u + \sigma w + \eta \omega$

$$X'_{i} = (1-\delta)X_{i} + \hat{u}(X_{i},X) + \sigma W_{i} + \eta \omega, \quad \text{for } i \in \{1,...,N\}$$

First order conditions + symmetric equilibrium

$$\gamma u(x,X) = \beta \mathbb{E} \left[p(X') + \gamma (1-\delta) u(x',X') \right]$$

Goal: Using economic theory to

Design $\mathcal{H}(\Theta)$ class for approximating u(x, X)?

General class of problems: A "big X, little x" dynamic programming

$$v(x,X) = \max_{u} \left\{ r(x,u,X) + \beta \mathbb{E} \left[v(x',X') \right] \right\}$$
s.t. $x' = g(x,u) + \sigma w + \eta \omega$

$$X' = G(X) + \Omega W + \eta \omega \mathbf{1}_{N}$$

- 1. x is the individual state of the agent.
- 2. X is a vector stacking the individual states of all of the N agents in the economy.
- 3. u is the control variable.
- 4. w is random innovation to the individual state, stacked in $W \sim \mathcal{N}(\mathbf{0}_N, \mathbf{I}_N)$ and where, w.l.o.g., $w = W_1$.
- 5. $\omega \sim \mathcal{N}(0,1)$ is a random aggregate innovation to all the individual states.

Permutation Groups

- A permutation matrix is a square matrix with a single 1 in each row and column and zeros everywhere else.
- Let S_N be the set of all n! permutation matrices of size $N \times N$. For example:

$$S_2 = \left\{ \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \right\}$$

- Multiplying vector $v \in \mathbb{R}^N$ by $\pi \in S_N$ reorders elements of v
- (If you know about this): S_N is the *symmetric group* under matrix multiplication.

Permutation-invariant dynamic programming

Definition

A 'big X, little x' dynamic programming problem is a permutation-invariant dynamic programming problem if, for all $(x, X) \in \mathbb{R}^{N+1}$ and all permutations $\pi \in \mathcal{S}_N$

1. The reward function *r* is **permutation invariant**:

$$r(x, u, \pi X) = r(x, u, X)$$

2. The deterministic component of the law of motion for X is permutation equivariant:

$$G(\pi X) = \pi G(X)$$

3. The covariance matrix of the idiosyncratic shocks satisfies

$$\pi\Omega=\Omega\pi$$

Main results I: Permutation invariance of the optimal solution

Proposition

The optimal solution of a permutation-invariant dynamic programming problem is permutation invariant. That is, for all $\pi \in \mathcal{S}_N$:

$$u(x,\pi X)=u(x,X)$$

and:

$$v(x, \pi X) = v(x, X)$$

Can u(x, X) permutation invariance guide $\mathcal{H}(\Theta)$ choice?

Curse of dimensionality in this example

Recall there are three separate sources of the "curse" here as we increase the number of agents:

- 1. Can we approximate u(x,X) for high dimensional $X \in \mathbb{R}^N$ without massive increases in the $\hat{\mathcal{X}}$ grid?
- 2. Given intuition that individual $X_i \in X$ have limited effect on u(x,X), how to calculate $\mathbb{E}[u(x',X')]$?
 - Look at $\mathbb{E}_W[u(x',X')|w,\omega]$ to condition on firm's idiosyncratic w aggregate shock ω .
 - Why conditioning on these two? They matter a lot. Now, can something similar to the law of large numbers happen?
- 3. What about the stationary solutions and transversality condition?
 - Euler equation have multiple solutions, some leading to non-stationary paths (I will come back to this).

Representation of permutation-invariant functions

Proposition

(based on Wagstaff et al., 2019) Let $f: \mathbb{R}^{N+1} \to \mathbb{R}$ be a continuous permutation-invariant function under S_N , i.e., for all $(x, X) \in \mathbb{R}^{N+1}$ and all $\pi \in S_N$:

$$f(x,\pi X)=f(x,X)$$

Then, there exist a latent dimension $L \leq N$ and continuous functions $\rho : \mathbb{R}^{L+1} \to \mathbb{R}$ and $\phi : \mathbb{R} \to \mathbb{R}^L$ such that:

$$f(x,X) = \rho\left(x, \frac{1}{N}\sum_{i=1}^{N}\phi(X_i)\right)$$

Representation of permutation-invariant functions: Discussion and intuition

$$u(x,X) = \rho\left(x, \frac{1}{N}\sum_{i=1}^{N}\phi(X_i)\right)$$

- This proposition should remind you of Krusell-Smith (1998), L=1, $\phi(X_i)=X_i$.
- Key benefit for approximation is the **representation** (ρ, ϕ) , **not explicit** dimensionality reduction.
- Fitting a ρ and ϕ rather than f directly leads to far better generalization on \mathcal{X} . Why?:
 - Imposing structure on $\mathcal{H}(\Theta)$, functions that know a lot about the economic problem.
- In practice: $L \ll N$ generalizes very well.

Representation of permutation-invariant functions: Discussion and intuition

- We have seen a **variation** of this in IO.
 - Exit/Entry problems, $X_i \in \{0, 1\}$.
- Remember the example with 266 states, binary values (zeros and ones)
 - $f(x,X): 2^{N+1} \to \mathbb{R}$.
 - If permutation invariant: I only care about the number of ones.
 - The dimensionality goes from 2^{N+1} to N+2.

$$f(x,X) = \hat{f}(x,\frac{1}{N}\sum_{i=1}^{N}X_i)$$

But in this paper X_i s are continuous variables.

Expected gradient bounded in N

We need to focus on specific functions to deal with high-dimensional expectations:

Definition (Expected gradient bounded in N)

Let $f: \mathbb{R}^N \to \mathbb{R}$ be a bounded function in N and $z \sim \mathcal{N}(\mathbf{0}_N, \mathbf{I}_N)$ be a normalized Gaussian random vector. The function f has its expected gradient bounded in N if there exists a C such that:

$$\mathbb{E}\left[\|\nabla f(z)\|^2\right] \leq \frac{C}{N},$$

where C does not depend on N.

$$\mathbb{E}_{W}\left[\|\nabla u(x',X')\|^{2}\right] \leq \frac{C}{N}$$

- W: the idiosyncratic shocks of the rest of the agents in the economy.
- The policy to be well-behaved (non-explosive gradients).
- Other agent's influence vanishes as the economy grows.

Main result II: Concentration of measure

Proposition

Suppose $z \sim \mathcal{N}(\mathbf{0}_N, \Sigma)$, where the spectral radius of Σ , denoted by $\rho(\Sigma)$, is independent of N, z^1 a draw from z, and $f: \mathbb{R}^N \to \mathbb{R}$ is a function with expected gradient bounded in N. Then:

$$\mathbb{P}\left(\left|f(z^1) - \mathbb{E}\left[f(z)\right]\right| \ge \epsilon\right) \le \frac{\rho(\Sigma)C}{\epsilon^2} \frac{1}{N}$$

- As Ledoux (2001) puts it: "A random variable that depends in a Lipschitz way on many independent variables (but not too much on any of them) is essentially constant."
- With concentration of measure, dimensionality is not a curse; it is a blessing.

Implication: We can calculate $\mathbb{E}_{W}[u(x',X')|w,\omega]$ with a *single draw* of idiosyncratic shocks W:

- $\mathbb{E}_W[u(x',X')|w,\omega] \approx u(x',X')|w,\omega$.
- Reducing an N + 1-dimensional conditional expectation to a 2-D one (with good approximation).

Summarizing the results

- The structure symmetry imposes on the functions leads to better **generalization**
 - Functions extrapolate better outside of the grid points $\hat{\mathcal{X}}$.
- Concentration of measures provides a fast method for calculating the conditional expectations.
 - Calculate with one draw of the idiosyncratic shocks (conditional on the aggregate shock).
- No non-heuristic algorithm exists to solve this problem.

Solving the Model

Design of $\mathcal{H}(\Theta)$: Deep learning architectures

$$u(x,X) = \rho\left(x, \frac{1}{N}\sum_{i=1}^{N}\phi(X_i)\right)$$

Three cases for ϕ :

- 1. Identity function: One moment $\rightarrow \phi(Identity)$.
- 2. Up to degree four polynomials: 4 moments $\rightarrow \phi(Moments)$.
- 3. A deep neural network for ϕ , with $L = 4 \rightarrow \phi(\text{ReLU})$.

If polynomials for ϕ : A finite set of moments à la Krusell-Smith.

- ullet In all cases, ho is a highly over-parameterized neural network with four layers.
- The baseline ϕ (Identity), ϕ (Moments), and ϕ (ReLU) have 49.4K, 50.3K, and 199.6K coefficients. ₂₇

Solution method follows "interpolation" methods

- 1. Pick: $\hat{\mathcal{X}}$ as simulated trajectories from X_0 :
 - Only need 100 to 1000 points regardless of dimensionality of the state space N.
 - Using economic insight (i.e., symmetry) gives us good generalization.
- 2. **Choose**: Design the $\mathcal{H}(\Theta)$ with ρ and ϕ as discussed:
 - ϕ (Identity), ϕ (Moments), and ϕ (ReLU).

Applying concentration of measures:

• One draw $\hat{W} = \{\hat{W}_1, \dots, \hat{W}_N\}$ of the idiosyncratic shocks. For a given $u(\cdot; \theta)$, and aggregate shock ω calculate:

$$X'_{i} = (1 - \delta)X_{i} + u(X) + \sigma \hat{W}_{i} + \eta \omega, \text{ for } i \in \{1, ..., N\}.$$

Solution method follows "interpolation" methods

Approximate the Euler residuals

$$\varepsilon(X; u(\cdot; \theta)) \equiv \gamma u(X; \theta) - \beta \mathbb{E}\left[P(X') + \gamma(1 - \delta)u(X'; \theta)\right]$$

using concentration of measures (one draw of W in X'). \square error analysis in N

3. **Fit**: The residuals $\varepsilon(X; u(\cdot; \theta))$, that is the "model" i.e., ℓ .

$$\min_{\theta \in \Theta} \sum_{X \in \hat{\mathcal{X}}} \varepsilon (X; \hat{u}(\cdot; \theta))^{2}$$

4. How to Verify/Test: Given the approximate solution simulate new paths from X_0 and check the Euler residuals (ε) .

Study two cases: linear (
u=1) and nonlinear (
u>1) demand functions

Case 1: Linear to verify algorithms and methods

- With $\nu = 1$, we have a linear demand function: $p(X) = 1 \frac{1}{N} \sum_{i=1}^{N} X_i$.
- It generates a Linear-Quadratic (LQ) dynamic programming problem (only the mean of X_i matters).
- We can find the exact u(x, X), LQ has algebraic solutions.
- The LQ solution gives us a benchmark against which we can compare our deep learning solution.
- The neural network figures learns the true solution, $u(x,X) = H_0 + H_1 \frac{1}{N} \sum_{i=1}^{N} X_i$, very quickly.

Euler residuals: Linear case

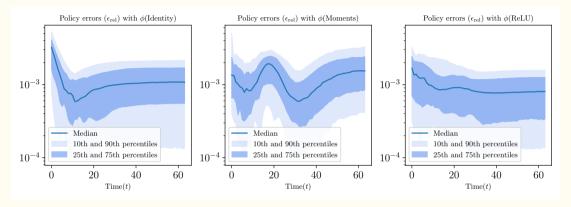

Figure 1: The absolute relative errors for $\nu=1$ and N=128 for $\phi(\text{Identity})$, $\phi(\text{Moments})$, and $\phi(\text{ReLU})$. The dark blue curve shows the median errors along equilibrium paths for 100 seeds and 32 different trajectories.

$$\varepsilon \equiv \left| \frac{u(X) - \hat{u}(X)}{u(X)} \right|$$

Equilibrium Paths: Linear case

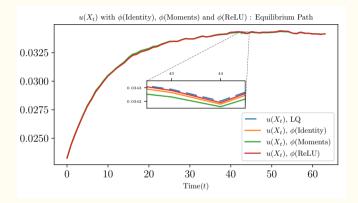

Figure 2: Comparison between baseline approximate solutions and the LQ solution for the case with $\nu=1$ and N=128.

Computation time: Linear case

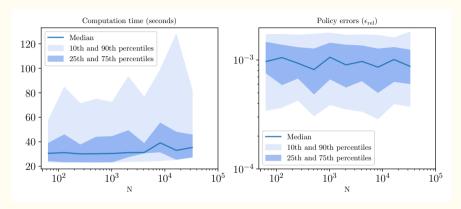

Figure 3: Performance of the $\phi(\text{ReLU})$ for different N (median value of 100 trials).

Case 2: Nonlinear case with no "closed-form" solution

- With $\nu > 1$, we have a nonlinear demand function: $p(X) = 1 \frac{1}{N} \sum_{i=1}^{N} X_i^{\nu}$.
- Notice how, now, the whole distribution of X_i matters.
- But we can still find the solution to this nonlinear case using exactly the same functional approximation and algorithm as before.
- ullet We do not need change anything in the code except the value of u.
- Since the LQ solution no longer holds, we do not have an exact solution to use as a benchmark, but can check residuals.
- ullet Same model and method. Computation time by ${\it N}$ nearly the same to linear case

Euler residuals: Nonlinear case

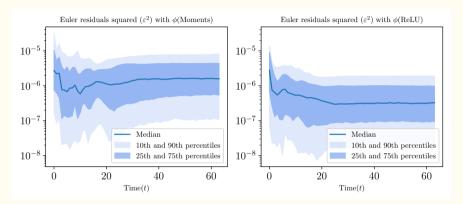

Figure 4: The Euler residuals for $\nu=1.5$ and N=128 for $\phi(\text{Moments})$ and $\phi(\text{ReLU})$. The dark blue curve shows the average residuals along equilibrium paths for 100 seeds and 32 different trajectories.

Equilibrium paths: Nonlinear case

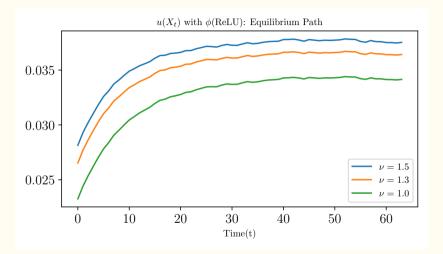

Figure 5: The optimal policy u along the equilibrium paths for $\nu = [1.0, 1.05, 1.1, 1.5]$ and N = 128. Each path shows the optimal policy for a single trajectory.

Some challenging question: Generalization puzzle

Question I: Generalization

- From statistical learning and numerical analysis we know:
 - More coefficients in the family of parametric functions H(Θ) leads to over-fitting and poor generalization (bias-variance trade-off).
 - We have $\approx 200K$ parameters, and < 1K grid points.
 - ullet The results indicate the opposite: More coefficients o better generalization.

How come we achieve great generalization?

Convergence results: Transversality condition and stationarity

Table 1: Simulating multiple seeds for different $\mathcal{H}(\Theta)$ with $\nu = 1$

		Success (%)	Early stopping failure (%)	Violation of transversality (%)	Overfitting (%)
Group	Description				
Identity	Baseline	48%	2%	50%	0%
Moments	Baseline	59%	2%	37%	2%
Deep Sets	Baseline	97%	0%	3%	0%

Some challenging questions: Multiplicity and transversality puzzle

Question II: Multiplicity and transversality

$$\gamma u(X) = \beta \mathbb{E} \left[p(X') + \gamma (1 - \delta) u(X') \right]$$

$$X'_i = (1 - \delta) X_i + u(X) + \sigma W_i + \eta \omega, \quad \text{for } i \in \{1, ..., N\}$$

with linear prices. Guess and verify with $u(X) \equiv H_0 + \frac{1}{N}H_1\sum_{i=1}^{N}X_i$

- The Euler equation is quadratic \rightarrow **two** solutions: $(H_0^-, H_1^-), (H_0^+, H_1^+)$:
 - $H_1^- < 0 \rightarrow$ stationary solution, $H_1^+ > 0 \rightarrow$ non-stationary solution.
 - We have no explicit device in our algorithm to weed out the second solution.

How come there is a strong bias towards the stationary solution

Understanding the **implicit bias** of deep neural networks answers both questions.

Summarizing the contribution

- **Method** for solving **high-dimensional** dynamic programming problems and competitive equilibria with idiosyncratic and aggregate shocks relying
 - Symmetry.
 - Concentration of measures: Dimensionality is a blessing not a curse.
- Using economic theory (i.e., exchangeability) and deep learning for function approximation with a huge # of parameters (>> grid points)
 - Achieve great generalization: key to alleviate the curse of dimensionality.
- Implementation
 - Can deal with 10000+ agents.
 - Can deal with 10000+ dimensional expectations with one Monte-carlo draw.

Spooky Boundaries at a Distance: Exploring

Transversality and Stability with

Deep Learning

Motivation

- Dynamic models usually require economic conditions eliminating explosive solutions (e.g., transversality or no-bubble).
 - These are variations of "boundary conditions" in ODEs and PDEs on forward-looking behavior.
 - Deterministic, stochastic, sequential, recursive formulations all require conditions in some form.
- These forward-looking boundary conditions are the key limitation on increasing dimensionality:
 - Otherwise, in sequential setups, we can easily solve high-dimensional initial value problems.
 - In recursive models accurate solutions are required for arbitrary values of the state variables.
- Question: Can we avoid precisely calculating steady-state, BGP, and stationary distribution, which
 are never reached, and still have accurate short/medium-run dynamics disciplined by these boundary
 conditions?

Contribution

- Show that **deep learning** solutions to many dynamic forward-looking models automatically fulfill the long-run boundary conditions we need (transversality and no-bubble).
 - We show how to design the approximation using economic insight.
- Solve classic models with known solutions (asset pricing and neoclassical growth) and show excellent short/medium term dynamics —even when **non-stationary** or with **steady state multiplicity**.
- Suggests these methods may solve high-dimensional problems while avoiding the key computational limitation.
 - We have to understand low-dimensional problems first.
- Intuition: DL has an "implicit bias" toward smooth and simple functions. Explosive solutions are not smooth.

So what is this implicit bias?

Deep learning optimizes in a space of functions

Remember

$$\min_{\theta \in \Theta} \sum_{x \in \hat{\mathcal{X}}} \ell(\hat{\psi}(\cdot; \theta), x)^2$$

- Deep learning: number of coefficients is much larger than the number of grid points.
- Since $M \gg D$, it is possible for $\hat{\psi}$ to interpolate and the objective value will be ≈ 0 .
- Since $M \gg D$ there are many solutions (e.g., θ_1 and θ_2),
 - Agree on the grid points: $\hat{\psi}(x; \theta_1) \approx \hat{\psi}(x; \theta_2)$ for $x \in \hat{\mathcal{X}}$.
- ullet Since individual heta are irrelevant it is helpful to think of optimization directly within ${\cal H}$

$$\min_{\hat{\psi}\in\mathcal{H}}\sum_{x\in\hat{\mathcal{X}}}\ell(\hat{\psi},x)^2$$

Deep learning and interpolation

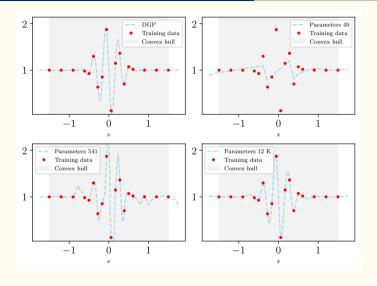

- For M large enough, optimizers **tend to** converge to **unique "simple"** $\hat{\psi}$ (w.r.t to some norm $\|\cdot\|_S$). Unique both in $\hat{\mathcal{X}}$ and \mathcal{X} . There is a **bias** toward a specific class of solutions.
- How to interpret: interpolating solutions for some functional norm $\|\cdot\|_S$

$$egin{aligned} \min_{\hat{\psi} \in \mathcal{H}} ||\hat{\psi}||_{\mathcal{S}} \ \mathrm{s.t.}\, \ell(\hat{\psi},x) = 0, \quad ext{ for } x \in \hat{\mathcal{X}} \end{aligned}$$

- Comp Sci literature refers to this as the **inductive bias** or **implicit bias**: optimization process is biased toward particular $\hat{\psi}$.
- Small values of $\|\cdot\|_S$ corresponds to flat solutions with small gradients (w.r.t. input).
- Characterizing $\|\cdot\|_S$ is an active research area in CS at the heart of deep learning theory.

Flat and smooth interpolation: Illustration

Deep learning and interpolation in practice

Reminder: in practice we solve

$$\min_{\theta \in \Theta} \sum_{x \in \hat{\mathcal{X}}} \ell \left(\hat{\psi}(\cdot; \theta), x \right)^2$$

- The smooth interpolation is imposed **implicitly** through the optimization process.
- No explicit norm minimization or penalization is required.

In this paper: we describe how (and when) the $\min_{\hat{\psi} \in \mathcal{H}} ||\hat{\psi}||_{\mathcal{S}}$ solutions are also the ones which automatically fulfill transversality and no-bubble conditions.

• They are disciplined by long-run boundary conditions. Therefore, we can obtain accurate short/medium-run dynamics.

Outline

To explore how we can have accurate short-run dynamics, we show deep learning solutions to

- 1. Classic linear-asset pricing model.
- 2. Sequential formulation of the neoclassical growth model.
- 3. Sequential neoclassical growth model with multiple steady states.
- 4. Recursive formulation of the neoclassical growth model.
- 5. Non-stationarity, such as balanced growth path.

Linear asset pricing

Sequential formulation

• Dividends, y(t), y_0 as given, and follows the process:

$$y(t+1) = c + (1+g)y(t)$$

• Writing as a linear state-space model with x(t+1) = Ax(t) and y(t) = Gx(t) and

$$x(t) \equiv \begin{bmatrix} 1 & y(t) \end{bmatrix}^{\top}, A \equiv \begin{bmatrix} 1 & 0 \\ c & 1+g \end{bmatrix}, G \equiv \begin{bmatrix} 0 & 1 \end{bmatrix}$$

• "Fundamental" price given x(t) is PDV with $\beta \in (0,1)$ and $\beta(1+g) < 1$

$$p_f(t) \equiv \sum_{j=0}^{\infty} \beta^j y(t+j) = G(I-eta A)^{-1} x(t).$$

Recursive formulation

With standard transformation, all solutions $p_f(t)$ fulfill the recursive equations

$$p(t) = Gx(t) + \beta p(t+1)$$

$$x(t+1) = Ax(t)$$
(1)

$$0 = \lim_{T \to \infty} \beta^T p(T)$$

$$x_0 \text{ given}$$
(3)

 x_0 given

That is, a system of two difference equations with one boundary and one initial condition.

- The boundary condition (3) is an **condition** necessary for the problem to be well-posed and have a unique solution.
 - It ensures that $p(t) = p_f(t)$ by imposing long-run boundary condition.
 - But without this assumption there can be "bubbles" with $p(t) \neq p_f(t)$, only fulfilling (1) and (2).
 - Intuition: system of $\{p(t), x(t)\}$ difference equations requires total of two boundaries or initial values to have a unique solution.

Solutions without no-bubble condition

Without the no-bubble condition:

• Solutions in this deterministic asset pricing model are of the form:

$$p(t) = p_f(t) + \zeta \beta^{-t}.$$

- For any $\zeta \geq 0$. The initial condition x(0) determines $p_f(t)$.
- There are infinitely many solutions.
- The no-bubble condition chooses $\zeta = 0$.

Interpolation problem: without no-bubble condition

- A set of points in time $\hat{\mathcal{X}} = \{t_1, \dots, t_{\mathsf{max}}\}.$
- A family of over-parameterized functions $p(\cdot; \theta) \in \mathcal{H}(\Theta)$.
- Generate x(t) using the law of motion and x(0), equation (2). In practice we minimize the residuals of the recursive form for the price:

$$\min_{\theta \in \Theta} \frac{1}{|\hat{\mathcal{X}}|} \sum_{t \in \hat{\mathcal{X}}} \left[p(t;\theta) - Gx(t) - \beta p(t+1;\theta) \right]^2 \tag{6}$$

- This minimization does not contain no-bubble condition. It has infinitely many minima.
- Does the implicit bias of over-parameterized interpolation weed out the bubbles? Yes.
- Intuition: bubble solutions are explosive, i.e., big functions with big derivatives.

Let's analyze this more rigorously.

Interpolation formulation: min-norm mental model

The min-norm interpretation (mental model) is:

$$\min_{p \in \mathcal{H}} \|p\|_{\mathcal{S}}$$
s.t. $p(t) - Gx(t) - \beta p(t+1) = 0$ for $t \in \hat{\mathcal{X}}$

$$0 = \lim_{T \to \infty} \beta^T p(T)$$

Where x(t) for $t \in \hat{\mathcal{X}}$ is defined by x(0) initial condition and recurrence x(t+1) = Ax(t) in (2)

• The minimization of norm $\|p\|_{\mathcal{S}}$ is the "inductive bias" toward particular solutions for $t \in [0, \infty] \setminus \hat{\mathcal{X}}$.

Is the no-bubble condition still necessary?

- To analyze, drop the no-bubble condition and examine the class of solutions.
- In this case, we know the interpolating solutions to (8) without imposing (9)

$$p(t) = p_f(t) + \zeta \beta^{-t} \tag{10}$$

Applying the triangle inequality

$$\|p_{f}\|_{S} \leq \|p\|_{S} \leq \|p_{f}\|_{S} + \zeta \|\beta^{-t}\|_{S}$$
(11)

- Relative to classic methods the "deep learning" problem now has a new objective, minimizing $\|p\|_S$.
- The new objective of minimizing the norm, makes the no-bubble condition **redundant**.

Min-norm norm formulation: redundancy of no-bubble condition

compare to $p_f(t)$ $\min_{p \in \mathcal{H}} ||p|| s$ s.t. $p(t) - Gx(t) - \beta p(t+1) = 0$ for $t \in \hat{\mathcal{X}}$

Given the no-bubble condition is automatically fulfilled, could solve the following given some \mathcal{H} and

$$\begin{array}{c|c}
\min_{p \in \mathcal{H}} & \|p\|_{\mathcal{P}} \\
\text{s.t.} & p(t)
\end{array}$$

• The $\hat{\mathcal{X}}$ does not need to be contiguous and $|\hat{\mathcal{X}}|$ may be relatively small. • Most important: no steady state calculated, nor large $T \in \hat{\mathcal{X}}$ required.

 $\min_{ heta \in \Theta} rac{1}{|\hat{\mathcal{X}}|} \sum_{t \in \hat{\mathcal{X}}} \left[p(t; heta) - Gx(t) - eta p(t+1; heta)
ight]^2$

Since law of motion is deterministic, given x(0) we generate x(t) with x(t+1) = Ax(t) for $t \in \hat{\mathcal{X}}$

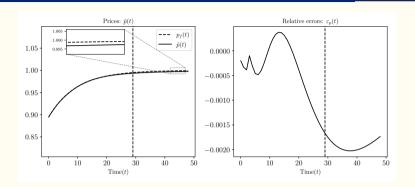

(12)

(13)

(14)

A reminder: in practice, given the $\hat{\mathcal{X}}$, we directly implement this as $p(\cdot;\theta) \in \mathcal{H}(\Theta)$ and fit with

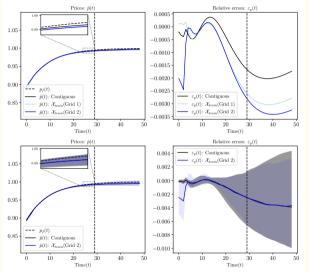

Results

- 1. Pick $\hat{\mathcal{X}} = \{0, 1, 2, ..., 29\}$ and t > 29 is "extrapolation" where c = 0.01, g = -0.1, and $y_0 = 0.8$.
- 2. Choose $p(t;\theta) = NN(t;\theta)$ where "NN" has 4 hidden layers of 128 nodes. $|\Theta| = 49.9K$ coefficients.
- 3. Fit using L-BFGS and PyTorch in just a few seconds. Could use Adam/SGD/etc.
- 4. Low generalization errors, even without imposing no-bubble condition.

$$\varepsilon_p(t) \equiv \frac{\hat{p}(t) - p(t)}{p(t)}$$

Contiguous vs. sparse grid

- Pick $\hat{\mathcal{X}}(\mathsf{Grid}\ 1) = \{0, 1, 2, 4, 6, 8, 12, 16, 20, 24, 29\}$ and $\hat{\mathcal{X}}(\mathsf{Grid}\ 2) = \{0, 1, 4, 8, 12, 18, 24, 29\}.$
- Contrary to popular belief, can use less grid points relative to alternatives.
- Hypothesis verified, the solutions agree on the seen and unseen grid points.

Neoclassical growth in sequence space

Sequential formulation

$$\max_{\{c(t), k(t+1)\}_{t=0}^{\infty}} \sum_{t=0}^{\infty} \beta^{t} u(c(t))$$
s.t.
$$k(t+1) = z(t)^{1-\alpha} f(k(t)) + (1-\delta)k(t) - c(t)$$

$$z(t+1) = (1+g)z(t)$$

$$k(t) \ge 0$$
(15)
(16)

$$0 = \lim_{T \to \infty} \beta^T u'(c(T)) k(T+1)$$

$$k_0, z_0 \text{ given}$$
(19)

- Preferences: $u(c) = \frac{c^{1-\sigma}-1}{1-\sigma}$, $\sigma > 0$, $\lim_{c\to 0} u'(c) = \infty$, and $\beta \in (0,1)$.
- Cobb-Douglas production function: $f(k) = k^{\alpha}$, $\alpha \in (0,1)$ before scaling by TFP z_t .
- Skip standard steps. . . Euler equation: $u'(c(t)) = \beta u'(c(t+1))[z(t+1)^{1-\alpha}f'(k(t+1)) + 1 \delta]$.

Interpolation problem: without transversality condition

- A set of points in time $\hat{\mathcal{X}} = \{t_1, \dots, t_{\mathsf{max}}\}.$
- A family of over-parameterized functions $k(\cdot; \theta) \in \mathcal{H}(\Theta)$.
- Generate z(t) using the law of motion and z(0), equations (17).
- Use the feasibility condition and define $c(t;k) \equiv z(t)^{1-\alpha} f(k(t)) + (1-\delta)k(t) k(t+1)$.

In practice we minimize the Euler and initial conditions residuals:

$$\min_{\theta \in \Theta} \left(\frac{1}{|\hat{\mathcal{X}}|} \sum_{t \in \hat{\mathcal{X}}} \lambda_1 \left[\underbrace{\frac{u'(c(t; k(\cdot, \theta)))}{u'(c(t+1; k(\cdot; \theta)))} - \beta \left[z(t+1)^{1-\alpha} f'(k(t+1; \theta)) + 1 - \delta\right]}_{\text{Euler residuals}} \right]^2$$

$$+ \lambda_2 \left[\underbrace{k(0; \theta) - k_0}_{\text{Initial condition residuals}} \right]^2)$$

• λ_1 and λ_2 positive weights.

Interpolation problem: without transversality condition

- This minimization does not contain the transversality condition.
 - Without the transversality condition it has infinitely many minima.
- No explicit norm minimization.
- Does the implicit bias weed out the solutions that violate the transversality condition? Yes.
- Intuition: The solutions that violate the transversality condition are big functions with big derivatives.

Let's analyze this more rigorously.

Interpolation formulation: min-norm mental model

 $||k||_S$

 $k \in \mathcal{H}$

s.t.
$$u'(c(t;k)) = \beta u'(c(t+1;k))[z(t+1)^{1-\alpha}f'(k(t+1)) + 1 - \delta]$$
 for $t \in \hat{\mathcal{X}}$

$$k(0) = k_0$$

$$0 = \lim_{T \to \infty} \beta^T u'(c(T;k))k(T+1)$$

$$c(t;k) \equiv z(t)^{1-\alpha}f(k(t)) + (1-\delta)k(t) - k(t+1)$$

Where z(t) for $t \in \hat{\mathcal{X}}$ is defined by z(0) initial condition and recurrence z(t+1) = (1+g)z(t).

(21)

(23)

(24)

(25)

Is the transversality condition still necessary? Case of g=0, z=1

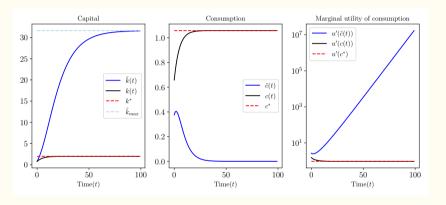

Sketch of the proof:

- Let $\{k(t), c(t)\}$ be the sequence of optimal solution.
- Let $\{\tilde{k}(t), \tilde{c}(t)\}$ be a sequence of solution that satisfy all the equations **except** transversality condition (24).
- 1. $\tilde{c}(t)$ approaches zero.
- 2. $\tilde{k}(t)$ approaches $\tilde{k}_{\max} \equiv \delta^{\frac{1}{\alpha-1}}$, and k(t) approaches $k^* \equiv \left(\frac{\beta^{-1}+\delta-1}{\alpha}\right)^{\frac{1}{\alpha-1}}$.
- 3. Both $\tilde{k}(t)$ and k(t) are monotone. $\tilde{k}_{\mathsf{max}} \gg k^*$. Therefore,

$$0\leq \|k\|_{\mathcal{S}}\leq \|\tilde{k}\|_{\mathcal{S}}.$$

Is the transversality condition still necessary? Case of g=0, z=1

Example: the violation of the transversality condition.

- The solution that violate the transversality are associated with "big" capital path.
- The new objective of minimizing the norm, makes the transversality condition **redundant**.

Min-norm formulation: redundancy of transversality condition

Given the transversality condition is automatically fulfilled, one could solve

$$\begin{aligned} & \underset{k \in \mathcal{H}}{\text{min}} & \|k\|_{\mathcal{S}} \\ & \text{s.t.} & u'(c(t;k)) = \beta u'(c(t+1;k)) \big[z(t+1)^{1-\alpha} f'(k(t+1)) + 1 - \delta \big] & \text{for } t \in \hat{\mathcal{X}} \\ & k(0) = k_0 \end{aligned}$$

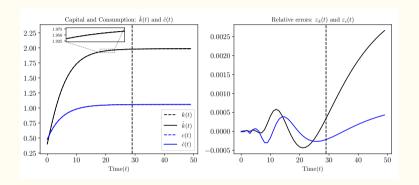

Reminder: in practice we solve

$$\min_{\theta \in \Theta} \left(\frac{1}{|\hat{\mathcal{X}}|} \sum_{t \in \hat{\mathcal{X}}} \lambda_1 \left[\frac{u'(c(t; k(\cdot, \theta)))}{u'(c(t+1; k(\cdot; \theta)))} - \beta \left[z(t+1)^{1-\alpha} f'(k(t+1; \theta)) + 1 - \delta \right] \right]^2$$

$$+ \lambda_2 \left[\underbrace{k(0; \theta) - k_0}_{\text{Initial condition residuals}} \right]^2 \right)$$

• $|\hat{\mathcal{X}}|$ may be relatively small, no steady state calculated, nor large $T \in \hat{\mathcal{X}}$ required.

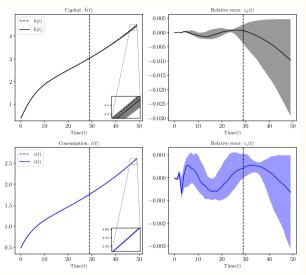

Results

- 1. Pick $\hat{\mathcal{X}} = \{0, 1, ..., 30\}$ and t > 30 is "extrapolation" $\alpha = \frac{1}{3}$, $\sigma = 1$, $\beta = 0.9$, g = 0.0, and $k_0 = 0.4$
- 2. Choose $k(t;\theta) = NN(t;\theta)$ where "NN" has 4 hidden layers of 128 nodes. $|\Theta| = 49.9K$ coefficients.
- 3. Fit using L-BFGS in just a few seconds. Comparing with value function iteration solution.
- 4. Low generalization errors, even without imposing the transversality condition.

Relative errors defined as
$$\varepsilon_c(t) \equiv \frac{\hat{c}(t) - c(t)}{c(t)}$$
, $\varepsilon_k(t) \equiv \frac{\hat{k}(t) - k(t)}{k(t)}$.

Growing TFP

- Pick same $\hat{\mathcal{X}}$ but now g = 0.02.
- Choose $k(t; \theta) = e^{\phi t} NN(t; \theta_{NN})$ where $\theta \equiv \{\phi, \theta_{NN}\} \in \Theta$ is the coefficient vector
 - Here we used economic intuition of problem to design the H(Θ) to generalize better.
- Non-stationary but can figure out the BGP.
- Learns the growth rate: $\phi \approx \ln(1+g)$
- Economic insight leads to great extrapolation!

The neoclassical growth model

with multiple steady states

Sequential formulation

$$\max_{\{c_{t}, k_{t+1}\}_{t=0}^{\infty}} \sum_{t=0}^{\infty} \beta^{t} u(c_{t})$$
s.t. $k_{t+1} = f(k_{t}) + (1 - \delta)k_{t} - c_{t}$

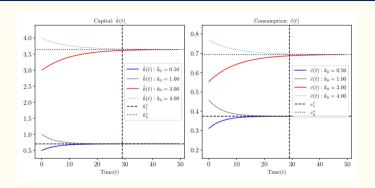

$$k_{t} \geq 0$$

$$0 = \lim_{T \to \infty} \beta^{T} u'(c_{T})k_{T+1}$$

$$k_{0} \text{ given.}$$

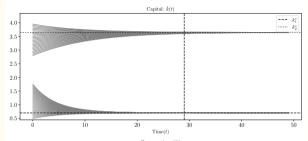

- 1. Preferences: $u(c) = \frac{c^{1-\sigma}-1}{1-\sigma}$, $\sigma > 0$, $\lim_{c\to 0} u'(c) = \infty$, and $\beta \in (0,1)$.
- 2. "Butterfly production function": $f(k) = a \max\{k^{\alpha}, b_1 k^{\alpha} b_2\}, \ \alpha \in (0, 1)$:
 - There is a kink in the production function at $k^* \equiv \left(\frac{b_2}{b_1-1}\right)^{\frac{1}{\alpha}}$.
 - This problem has two steady states, k_1^* and k_2^* and their corresponding consumption levels c_1^* and c_2^* .

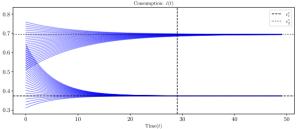

Results

- 1. Pick $\hat{\mathcal{X}} = \{0, \dots, 30\}$, $\alpha = \frac{1}{3}$, $\sigma = 1$, $\beta = 0.9$, g = 0.0, a = 0.5, $b_1 = 3$, $b_2 = 2.5$ and $k_0 \in \{0.5, 1.0, 3.0, 4.0\}$
- 2. Choose $k(t;\theta) = NN(t;\theta)$ where "NN" has 4 hidden layers of 128 nodes. $|\Theta| = 49.9K$ coefficients.
- 3. Fit using Adam optimizer.

Results: different initial conditions

- Different initial conditions in k₀ ∈ [0.5, 1.75] ∪ [2.75, 4].
- In the vicinity of k₁* and k₂* the paths converge to the right steady-states.
 - The implicit bias picks up the right path.
- Low generalization errors, even without imposing the transversality condition.

Conclusion

- Solving functional equations with deep learning is an extension of collocation/interpolation methods.
- With massive over-parameterization, optimizers tend to choose those interpolating functions which are not explosive and with smaller gradients (i.e., inductive bias).
- Over-parameterized solutions automatically fulfill forward-looking boundary conditions:
 - Shedding light on the convergence of deep learning based solutions in dynamic problems in macroeconomics.
- If we solve models with deep-learning without (directly) imposing long-run boundary conditions,
 - Short/medium-run errors are small, and long-run errors after "we are all dead" are even manageable.
 - Long-run errors do not affect transition dynamics even in the presence of non-stationarity and steady-state multiplicity.
 - Gives hope for solving high-dimensional models still disciplined by forward-looking economic assumptions.

Appendix

Definition (Bounded functions in N)

Let:

$$\mathcal{L}(M) \equiv \{ y \in \mathbb{R}^N : |y_i| \le M \ \forall i = 1, \dots, N \}$$

be an N-dimensional hypercube in \mathbb{R}^N . A function $f: \mathbb{R}^N \to \mathbb{R}$ is bounded in N if for every M there exists K_M such that

$$\sup_{y \in \mathcal{L}(M)} |f(y)| < K_M,$$

where K_M is a constant that does not depend on N, but may depend on M.

- Example $f(y) = \frac{1}{N} \sum_{i=1}^{N} y_i \to \sup_{y \in \mathcal{L}(M)} |f(y)| < M$.
- To avoid $f(y) = \sum_{i=1}^{N} y_i \to \sup_{y \in \mathcal{L}(M)} |f(y)| < NM$.

Concentration of measure is the bless of dimensionality

In the linear case we know the closed form solution for u

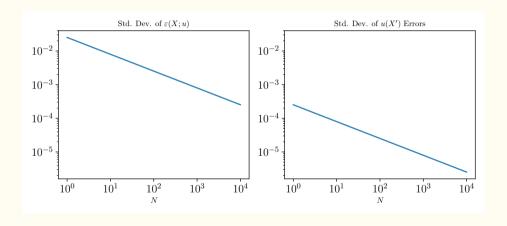

$$\hat{arepsilon}(X;u) - 0 \sim \mathcal{N}\left(0, rac{\sigma_{arepsilon}^2}{N}
ight)$$

$$u(\hat{X}') - \mathbb{E}\left[u(X') \mid \omega\right] \sim \mathcal{N}\left(0, rac{\sigma_{u}^2}{N}
ight)$$

- ullet Conditional expectation becomes constant as N gets large.
 - One single Monte-carlo draw of the idiosyncratic shocks is enough.

Analytic euler error due to the concentration of measure

Parameters

•
$$\gamma=$$
 90, $\beta=$ 0.95, $\sigma=$ 0.005, $\eta=$ 0.001.

Implicit bias: More details

Let ψ_1 and ψ_2 be two differentiable function from a compact space $\mathcal X$ in $\mathbb R$ to $\mathbb R$ such that

$$\int_{\mathcal{X}} \left| \frac{d\psi_1}{dx} \right|^2 dx > \int_{\mathcal{X}} \left| \frac{d\psi_2}{dx} \right|^2 dx$$

then

$$\|\psi_1\|_{\mathcal{S}} > \|\psi_2\|_{\mathcal{S}}.$$

Recently shown the optimizers (first order e.g. SGD) regularize Sobolev semi-norms: Ma, Ying (2021).
